Measuring risk

Measuring risk

- Value-at-Risk
- Managing portfolio risk

- ► Risk is the possibility of a loss
- ► Volatility does not only capture negative outcomes below the mean, but also positive outcomes above the mean
- A risk measure is needed that focuses exclusively on losses
- ► The risk measure should capture the size losses better than volatility, especially fat tails

Value-at-risk Slide 4 of 20

- A risk measure could be the reasonable amount that can be lost within a given time horizon
- ► What is reasonable will depend on the implications losses have and the risk aversion of the user
- ► The more severe the impact and the more risk averse the user is, the smaller the loss beyond what is reasonable should be
- ► Reporting risk as potential losses has the advantage that the result is intuitively understood by decision-makers

Probability of large losses

- ► The Value-at-Risk is a statement that the loss will not exceed this amount with a probability of *c* over the next *T* time periods.
- lacktriangle Losses will only be larger than the Value-at-Risk with probability 1-c
- A loss needs to be defined relative to a benchmark, which could be the status quo (absolute loss) or the expected outcome (relative loss)
- In financial markets returns are small and for simplicity the relative loss is commonly used

Definition of Value-at-Risk

- ▶ Define a threshold such that the probability that the outcome is below this threshold is given by a certain value
- $Prob(V < \hat{V}) = 1 c$
- ► The Value-at-Risk is then given as the difference between this threshold and the expected outcome
- $ightharpoonup VaR = E[V] \hat{V}$
- ightharpoonup Value-at-Risk is the estimation of the 1-c-quantile of the distribution of outcomes

Value-at-Risk as a quantile

Value-at-Risk for normal distributions

- ▶ If the distribution is normal, the 1-c-quantile can be determined using the quantiles of the standard normal distribution
- ► The standard normal distribution needs to be adjusted by the standard deviation of outcomes and the amount invested
- $ightharpoonup VaR = \alpha \sigma V_0$
- ► The choice of quantile will depend on the risk aversion of the investor
- ► The more risk averse an investor is, the lower the quantile to cover a wider range of possible losses

Impact of assets on portfolio risk

 $=2Cov[R_i,R_P]\equiv2\sigma_{iP}$

- Investors usually hold a portfolio of assets and using its standard deviation we obtain the Value-at-Risk: $VaR=\alpha\sigma_pV_0$
- Portfolio variance:
 $$\begin{split} \sigma_P^2 &= \sum_{i=1}^N \sum_{j=1}^N \omega_i \omega_j \sigma_{ij} \\ &= \sum_{i=1}^N \omega_i^2 \sigma_i^2 + \sum_{i=1}^N \sum_{j=1, j \neq i}^N \omega_i \omega_j \sigma_{ij} \\ \Rightarrow & \frac{\partial \sigma_P^2}{\partial \omega_i} = 2\omega_i \sigma_i^2 + 2\sum_{j=1, j \neq i}^N \omega_j \sigma_{ij} \\ &= 2Cov \left[R_i, \omega_i R_i + \sum_{j=1, j \neq i}^N \omega_j R_j \right] \end{split}$$

Marginal Value-at-Risk

We are interested in how the Value-at-Risk changes as the weight of assets in the portfolio changes

- ightharpoonup This expression is referred to as the marginal Value-at-Risk, ∂VaR_i
- If we change the weight of asset i by a small amount, the Value-at-Risk changes by ∂VaR_i

Changes to the Value-at-Risk of a portfolio

- ► If we change the weight more than marginally, we can use a linear approximation of the change
- ► The total change in the Value-at-Risk is equal to the sum of the changes for each individual asset
- If we only rearrange the weights, the total changes in the weights must be zero: $\sum_{i=1}^N \Delta\omega_i = 0$

Value-at-risk Slide 15 of 20

Changing portfolio risk

- ▶ To reduce the risk of a portfolio, reduce the weight of those assets with high marginal Value-at-Risks, high β_i , and increase those with low marginal Value-at-Risk, low β_i
- ▶ Reducing the weight of an asset with a high β_i reduces the Value-at-Risk considerably and increasing the weight of an asset with low β_i increases it by less, leading to a reduction in the Value-at-Risk
- ► The larger the difference between these two assets is, the bigger the impact on the Value-at-Risk
- ▶ For two assets the solution is unique, but for more assets many solutions exist
- Not always is it desirable or possible to change the weight of an asset, strategic investment decisions might become relevant
- ► The marginal Value-at-Risk gives indication which assets to choose most efficiently

The benefits of using Value-at-Risk

- Value-at-Risk can be used to measure risk in an intuitive way by focussing exclusively on losses
- ▶ It provides a framework in which risks of individual assets in a portfolio can be assessed
- Portfolios can be re-arranged to meet risk limits and the marginal Value-at-Risk can be used to identify assets that should change weights

Value-at-risk Slide 18 of 20

Limits of Value-at-Risk

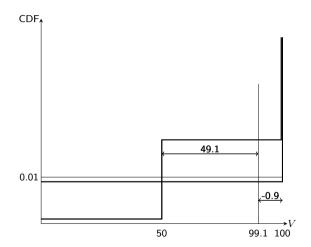

- ➤ You have a single loan worth £100m with a probability of default 0.9%, the amount lost in case of default is the full amount
- \Rightarrow 99% VaR: £-0.9m
- ► Suppose now we have two loans of £50m each with the same default rate and defaults are independent
- ▶ Prob (1 default occurs)= $2 \times \text{Prob} (\text{default}) (1 \text{Prob} (\text{default})) = 0.017838$
- Prob (2 defaults occur) = Prob (default)² = 0.000081
- \Rightarrow 99% VaR: £49.1m
- ⇒ The VaR increases with diversification
