# Aim of portfolio insurance

- Measuring risk and adjusting portfolios to achieve a certain level of risk does not prevent losses
- In many cases investors want to ensure a certain minimum value of their investment at the end of their time horizon
- This can be driven by regulatory requirements or the need to meet given obligations, for example pension payments
- In principle derivatives can be used to achieve this aim as they allow to hedge these risks
- In many cases derivatives are not readily available or the number of instruments that need to be used is prohibitively high

Slide 2 of 9

# Buy-and-hold strategy

An investor wants to ensure that the final value of his investment exceeds some threshold, expressed relative to his current value

 $\blacktriangleright V_T \ge \alpha V_0$ 

- ► The investor invests into the risk-free asset so this final value is ensured is ensured:  $B_t = \alpha V_0 e^{-r(T-t)}$
- $\Rightarrow B_T = \alpha V_0$
- ▶ The remainder is invested into the risky asset:  $C_t = V_t B_t = V_t \alpha V_0 e^{-r(T-t)}$
- ▶ This implies usually a low investment into risky assets or even a short position

# Maximum loss of the risky asset

- Assume the risky asset cannot make losses exceeding a certain threshold before it can be liquidated
- ▶ This risk of such a loss may evaluated using Value-at-Risk or other risk measures
- With Value-at-Risk as a risk measure this threshold would be the reasonable loss the investor could make, the Value-at-Risk itself

- ▶ The amount not invested into the risk-free asset,  $C_t = V_t B_t$ , is called a cushion and the investment into the risk-free asset is the floor
- The investor will always be guaranteed to obtain the floor, plus any accumulated interest
- ▶ The investment strategy is to invest  $mC_t$  into the risky asset and  $B_t = V_t mC_t$ into the risk-free asset

## Worst case scenario

The worst case scenario is that the risky asset loses its maximum value and the risk free investment yields its return for certain

$$V_{t+1} \ge V_t - \gamma m C_t + r \left( V_t - m C_t \right)$$

$$\Rightarrow V_{t+1} = C_{t+1} + B_{t+1} \ge V_t - \gamma m C_t + r (V_t - m C_t) = C_t + B_t - \gamma m C_t + r (C_t + B_t - m C_t) = C_t (1 + r - m (\gamma + r)) + (1 + r) B_t$$

► If we keep the investments constant, then  $B_{t+1} = (1+r) B_t$ ⇒  $C_{t+1} \ge C_t (1+r-m(\gamma+r))$ 

# Optimal investment into the risky asset

- ► If the investor starts with a cushion  $C_0 = V_0 \alpha V_0 e^{-rT} = (1 \alpha e^{-rT}) V_0$ , a positive cushion ensures that the total investments meet the condition that  $V_T \ge \alpha V_0$
- $\Rightarrow 1 + r m\left(\gamma + r\right) > 0$
- $\Rightarrow m < \frac{1+r}{\gamma+r} \approx \frac{1}{\gamma}$
- $\blacktriangleright$  As assets can at most lose all their value,  $\gamma < 1$  and m > 1
- The investor can invest more into the risk-free asset than in a buy-and-hold strategy

# Constant proportion portfolio insurance

- As the investment consists of a fixed multiple m of the cushion invested into the risky asset, it is called the Constant Proportion Portfolio Insurance (CPPI)
- As the cushion changes every time period due to the value of the risky asset changing, the amounts invested into risky assets changes constantly
- This requires a continuous adjustment of the wights between risky and risk-free assets

- As the minimum value of the investment at the end of the time horizon is ensured, but its value can be higher, CPPI is comparable to hedging the portfolio with a Put option having a strike price of  $\alpha V_0$
- As not the entire investment is in the risky asset, the payoff at maturity will be different to that of a hedge with put options, but no premium is payable either
- Transaction costs of adjusting the portfolio constantly can be prohibitive
- CPPI can be used as an alternative to the use of derivatives or where derivatives are not available
